One of the major challenges in designing with any new material, and particularly with advanced composite materials, is the fidelity of material design allowables. In the case of composite materials, the concern arises from the inherent nature of these materials, i.e., their heterogeneous make-up and the various factors that affect their properties in a specific design environment. Composites have various scales – micro, macro, laminate and structural, as well as numerous other fabrication related parameters. Many advanced composites in aerospace applications involve complex two- and three-dimensional fiber architectures and requires high-temperature processing. Since there are uncertainties associated with each of these, the observed behavior of composite materials shows scatter. Evaluating the effect of each of these variables on the observed scatter in composite properties solely by testing is cost and time prohibitive. One alternative is to evaluate these effects by computational simulation.

The authors have developed probabilistic composite micromechanics techniques by combining woven composite micromechanics and Fast Probability Integration (FPI) techniques to address these issues. In this paper these techniques will be described and demonstrated through selected examples. Results in the form of cumulative distribution functions (CDF) of the composite properties of a MI (melt-infiltrated) SiC/SiC (silicon carbide fiber in a silicon carbide matrix) composite will be presented. A CDF is a relationship defined by the value of the property (the response variable) with respect to the cumulative probability of occurrence. Furthermore, input variables causing scatter are identified and ranked based upon their sensitivity magnitude. Sensitivity information is very valuable in quality control. How these results can be utilized to develop design allowables so that these materials may be used by structural analysts/designers will also be discussed.

Background

- temperature ceramic matrix composites (CMC's) performance applications that operate in harsh are candidate materials for a variety of high-Advanced composites, specifically highenvironments.
- advanced composites, is the fidelity of material One of the major challenges in designing with any new material, and particularly with design parameters.
- Composite materials are heterogeneous in their properties in a specific design environment. make-up and various factors affect their

General Observations

- numerous other fabrication related parameters. Composites have many scales - micro, macro, laminate and structural, They also involve
- and generally require a complex multi-step hightwo- or three-dimensional fiber architectures Many advanced composites involve complex temperature processing.
- Since there are uncertainties involved with each composite material exhibits significant scatter. of these steps, the observed behavior of
- uncertainties in each of these variables solely by Evaluating the effect of the influence of testing is cost/time prohibitive.

Objectives

- Design the material including uncertainties in constituent as well as fabrication related parameters
- Design structural components in the presence of well as uncertainties in the material properties. uncertainties due to loading, environment as
- Develop quantitative tools for risk assessment of new structural designs using these advanced composite materials.

Technical Challenges

- Cost of generating statistically meaningful data is prohibitive, particularly for advanced hightemperature composites.
- Sparse data on uncertainty distributions.
- needed to provide quantifiable risk assessment). methods (i.e. efficient design algorithms/tools High computation burden of probabilistic

Technical Challenges (contd.)
